Introduction

Recent estimates suggest that over 29 million individuals in the United States exhibit some degree of hearing impairment (National Institutes of Deafness and Communication Disorders (NIDCD). A major consequence of sensorineural hearing loss (SNHL) is communicative difficulty, especially with the addition of noise and/or reverberation (Dubno, Dirks and Morgan 1984; Hawkins and Yacullo 1984; Suter 1985; Helfer and Wilber 1990; Crandell 1991; Helfer and Huntley 1991; Needleman and Crandell 1995; Killion 1997a; Moore 1997). Unfortunately, conventional amplification with omnidirectional microphone technology may provide little or no improvement to the signal-to-noise ratio (SNR) in adverse listening environments (Duquesnoy and Plomp 1983; Plomp 1986; Crandell and Smaldino 2000; 2001). In fact, a lack of perceptual improvement in noisy listening environments is one of the major reasons why individuals with SNHL report dissatisfaction with and reject amplification (Kochkin 1994). At present, there are various technologies that have been shown to improve speech recognition in poor listening environments. These technologies include directional microphones and personal frequency modulation (FM) systems (Hawkins and Yacullo 1984; Hawkins 1984; Fabry 1994; Valente, Fabry and Potts 1995; Gravel, Fausel, Lisowski and Chobot 1999; Kuk, Kollofski, Brown, Melum and Rosenthal 1999; Preves, Sammeth and Wynne 1999; Rickettts and Dhar 1999; Pumford, Seewald, Scollie and Jenstad 2000; Ricketts, 2000a; 2000b; Valente, Schuman, Potts and Beck 2000; Ricketts, Lindley and Henry 2001).

Directional microphones are typically designed to provide less amplification to signals originating from the rear and sides relative to signals arriving from the front, which is where the speaker will ideally be located. Numerous investigations have demonstrated that directional microphone technology can significantly improve the speech recognition ability of individuals with SNHL, particularly in noisy listening environments relative to unaided or aided listening with the use of an omnidirectional microphone (Valente, Fabry and Potts 1995; Gravel, Fausel, Lisowski and Chobot 1999; Kuk, Kollofski, Brown, Melum and Rosenthal 1999; Preves, Sammeth and Wynne 1999; Rickettts and Dhar 1999; Pumford, Seewald, Scollie and Jenstad 2000; Ricketts, 2000b; Valente, Schuman, Potts and Beck 2000; Rickettts, Lindley and Henry 2001). Past investigations have demonstrated that the use of directional microphone technology can improve speech recognition in noise by as much as 3 to 8 dB over omnidirectional microphone technology in the same hearing instrument depending on microphone location, type of noise, test materials, reverberation, etc. (Hawkins and Yacullo 1984; Valente, Fabry and Potts 1995; Gravel, Fausel, Lisowski and Chobot 1999; Rickettts and Dhar 1999; Pumford, Seewald, Scollie and Jenstad 2000; Valente, Schuman, Potts and Beck 2000).

Personal FM systems also been shown to have the capability to significantly improve the speech recognition ability of individuals with SNHL (Hawkins 1984; Fabry 1994). Past investigations have demonstrated that FM technology can improve speech recognition in noise by as much as 10 to 20 dB over the unaided listening condition (Crandell and Smaldino 2000; 2001). With a personal FM system, the
speaker’s voice is picked-up via a FM wireless microphone located near the speaker’s mouth, where the effects of reverberation, distance, and noise are minimal. The FM system converts the acoustic signal to an electrical waveform at the microphone, and the signal is transmitted via FM signal, from the transmitter to the receiver. Both the transmitter and the receiver are tuned to the same transmitting and receiving frequency. At the receiver’s end, the electrical signal is amplified, converted back to an acoustical waveform, and conveyed to the listener. A recent, and increasingly popular, method for coupling FM systems to listeners with hearing impairment is via an “audio boot” coupled to a BTE hearing aid. This type of technology, such as the Phonak MicroLink, allows the user to convert his/her personal hearing aid into a FM system simply by attaching the audio boot and using a FM transmitter. Typically, such systems enable the user to have three settings: (1) FM only; for the purpose of focusing primarily on the talker; (2) environmental microphone (EM) only; for the purpose of listening to all individuals in the immediate listening environment as well as monitoring his/her own voice, and (3) FM + EM for listening to both the speaker as well as other individuals in that listening environment.

Despite the documented enhancement in speech recognition with directional microphones and FM technologies, to date, only one investigation has attempted to compare these technologies. Hawkins (1984) evaluated the effect of various hearing aid and FM system configurations on speech recognition in noise. Nine children with bilateral, mild to moderate SNHL served as study participants. These subjects used a Phonic Ear 805 CD BTE hearing instrument that had the capability to switch between omnidirectional and directional microphone modes. The Phonic Ear 441T microphone transmitter and the Phonic Ear 445R FM receiver served as the FM system. Speech recognition was assessed using spondees and Phonetically Balanced Kindergarten (PB-K) words presented in a classroom with a reverberation time of 0.6 sec. Speech was delivered from a loudspeaker located 2 m from the child at 0° azimuth. Speech noise was presented from a loudspeaker located 4 m from the child at 180° azimuth. Speech recognition was assessed in the following conditions: (1) monaural hearing aid in the omnidirectional microphone mode; (2) monaural hearing aid in the directional microphone mode; (3) binaural hearing aids in the omnidirectional microphone mode; (4) binaural hearing aids in the directional microphone mode; (5) FM only connected via a neck loop to a monaural hearing aid with a directional microphone on the FM transmitter; (6) FM only connected via a silhouette inductor to a monaural hearing aid with a directional microphone on the FM transmitter; (7) FM only connected via direct audio input (DAI) to a monaural hearing aid with a directional microphone on the FM transmitter; (8) FM only connected via DAI to a monaural hearing aid with an omnidirectional microphone on the FM transmitter; (9) FM plus EM with no attenuation connected via DAI to a monaural hearing aid in the omnidirectional microphone mode; (10) FM plus EM with no attenuation connected via DAI to binaural hearing aids in the omnidirectional microphone mode; and (11) FM plus EM with no attenuation connected via DAI to binaural hearing aids in the directional microphone mode. Results of this study suggested that FM technology does significantly improve speech recognition in noise when compared to any of the hearing aid alone arrangements (11.8 dB to 18.4 dB improvement). Additionally, FM only strategies were significantly better than any of the FM plus EM arrangements (7.9 to 16.9 dB). Finally, for most listening conditions, the FM plus EM arrangements were not significantly better than any of the hearing aid alone conditions.

Unfortunately, while an important and seminal investigation, several experimental limitations existed in that study which preclude the generalization to these data to current fitting options for patients with mild to moderate SNHL. First, Hawkins (1984) utilized only a single noise source located at 180 from the subject. It is well recognized that a single noise source is not typical of everyday listening environments that contain multiple noise sources (Valente, Schuman, Potts and Beck 2000; Ricketts, 2000). Thus, any reported FM advantages may not be similar in “real world” listening environments. Second, the study contained relatively few subjects as Hawkins (1984) only evaluated the speech recognition of nine children with SNHL. Additionally, these hearing aids utilized earlier directional microphone technology. In recent years, directional microphone technology has improved significantly with the advent of improved directional microphone components, dual-microphone technology, the D-mic™, analog to digital converters, real-time calibration of dual-microphones, wider and smoother frequency responses, adaptive microphones, etc. (Valente, 2000).
Thus, it is not known whether the difference reported by Hawkins (1984) between directional microphones and FM systems would remain with advanced directional microphone technology and the introduction of digital signal processing (DSP). Finally, at the time of the investigation, relatively obsolete FM technology was used. As previously mentioned, Phonak Corporation developed a new personal FM system receiver, the Phonak MicroLink, which does not utilize wires or a body-worn box like its predecessors. This lack of accessories is more cosmetically appealing and as such is growing in popularity in the FM market. Although one would assume that this type of product would also enhance speech recognition performance in noise, at this point in time, there no data is available to demonstrate this. With these considerations in mind, the purpose of this study was to examine the speech recognition ability in noise of adults with mild to severe SNHL utilizing current directional microphone and FM technology. Since there is limited empirical data comparing directional microphones and FM technologies, this investigation examined numerous configurations of both technologies. Specifically, speech recognition was assessed, using the Hearing in Noise Test (HINT) (Nilsson, Soli and Sullivan 1994) with diffuse noise, in the following listening conditions:

1. binaural unaided;
2. binaural Phonak Claro 311 dAZ BTE hearing aids alone in omnidirectional microphone mode;
3. binaural Phonak Claro 311 dAZ BTE hearing aids alone in directional (adaptive) microphone mode;
4. monaural digital Phonak Claro 311 dAZ BTE HA utilized with one Phonak MicroLink FM receiver with the EM attenuated (FM only mode) and one Phonak Claro 311 dAz BTE HA in the omnidirectional microphone mode worn on the opposite ear; and;
5. binaural digital Phonak Claro 311 dAZ BTE hearing aids utilized with binaural Phonak MicroLink FM receivers with the EM attenuated (FM only mode).

Methods

Subjects

Subjects were recruited from the audiology clinics at two sites. Site I was the University of Florida in Gainesville, Florida and Site II was Washington University School of Medicine in St. Louis, Missouri. At Site I, twenty-two subjects were evaluated, of which 15 (68%) were male and seven (32%) were female. These subjects ranged in age from 24 to 84 years, with a median age of 73 years. At Site II, twenty-three subjects were evaluated, of which 13 (57%) were male and 10 (43%) were female. These subjects ranged in age from 34 to 81 years, with a median age of 73 years. An independent samples t-test revealed that there was no statistically significant difference between the two sites in terms of age (p = 0.646).

Pure-tone air-conduction and bone-conduction thresholds were obtained bilaterally. Test results revealed mean pure-tone thresholds consistent with a mild sloping to severe SNHL bilaterally and a moderate sloping to severe SNHL bilaterally at Sites I and II respectively (see figure 1). Word recognition scores (WRS) were also obtained at the Most Intelligible Level (MIL) on each ear, using recorded NU-6 word lists, for all study participants. Test results revealed mean word recognition scores (±1 SD) of 80.2% (±13%) and 79.4% (±11%) for the right and left ears respectively at Site I and 73.4% (±11%) and 77.0% (±7%) at Site II. These were no significant differences between the two ears in terms of pure-tone average (PTA) at Site I (p = 0.789) and at Site II (p = 0.730)

Figure 1. Mean pure-tone air-conduction thresholds for Site 1 (upper curve) and Site II (lower curve). Each curve represents the mean air conduction threshold of the right and left ears for each site.
and WRS at Site I (p = 0.971) and Site II (p = 0.157). An independent samples t-test, however, revealed that there were statistically significant differences between the two sites in terms of PTA for both ears (p = 0.000). There were no statistically significant differences between the two sites in terms of WRS for the right (p = 0.101) and the left (p = 0.460) ears. All subjects met the following inclusion/exclusion criteria:

1. Ear inspection via otoscopy within normal limits.
2. Normal middle ear function bilaterally (+/− 100 decaPascals [daPa]) as indicated by tympanometry.
3. No evidence of conductive or retrocochlear pathology as indicated by pure-tone testing and immittance measurements.
4. No air-bone gap greater than 10 dB at any test frequency as indicated by pure-tone test results.
5. Slight (20 to 40 dB HL) – to-severe (65 to 85 dB HL) high frequency or flat SNHL as indicated by pure-tone test results (250 Hz to 8000 Hz, including 3000 and 6000 Hz).
6. Symmetrical hearing loss that does not differ by more than 15 dB at more than one audiometric test frequency as indicated by pure-tone test results.
7. Word recognition scores of 50% or better in quiet as assessed by recorded versions of NU-6 monosyllables at the subject’s MIL.
8. Motivated to try amplification as reported by the participant.
9. Native speaker of English as reported by the participant.
10. Intact mental status as measured by the Short-Portable Mental Status Questionnaire (SPMSQ).
11. No history of chronic or terminal illness, psychiatric disturbance, or senile dementia as reported by the participant.
12. No history of being bedfast/chairfast as reported by the participant.
13. Not home or nursing bound.
14. No history of stroke or cerebral vascular disorder with a paresis or aphasia as reported by the participant.
15. Willing and able to give written informed consent to participate in this investigation, as noted by their signature on the Informed Consent to Participate in Research document.

Amplification Systems

All subjects were fit with digital Phonak Claro 311 dAZ BTE hearing aids binaurally. All earmolds had select-a-vent (SAV) venting and #13 or 3 mm horn tubing. In addition to the hearing aids, subjects were fit with Phonak MicroLink MLS FM receivers bilaterally. These FM receivers attach to the bottom of a BTE hearing aid and may be utilized in either the “FM only” mode, which attenuates the hearing aid microphone by 20 dB, or in the FM plus hearing aid mode, which allows for FM input and input of environmental sounds via the hearing aid microphones simultaneously at the same output level. The Phonak TX3 HandyMic FM transmitter served as the FM transmitter. This transmitter has three microphone options: (1) **Wide Angle**, which picks up sounds arriving from all directions around the transmitter microphone (omnidirectional); (2) **Zoom**, which provides reduced amplification to signals arriving from the rear (cardioid); and (3) **SuperZoom**, which provides reduced amplification to signals originating from the rear and the sides (hypercardioid). The hearing aids were fit as recommended via the Desired Sensation Level (DSL) (Seewald, 2000) prescriptive fitting formula on the Phonak Fitting Guideline (PFG) Version 7.3 software. All fittings were compared to prescriptive targets using probe-microphone measures. Additionally, all subjects successfully used their amplification systems for at least 30 days prior to assessing speech recognition in noise.

Speech Stimuli

Speech recognition was assessed using the Hearing in Noise Test (HINT) sentences (Nilsson, Soli and Sullivan 1994). The HINT consists of 25 lists of 10 sentences each. Each sentence is six to seven syllables in length and is at a first grade reading level (Nilsson, Soli and Sullivan 1996). All sentence lists are equivalent in length, phonemic content, and difficulty level in both quiet and noise (Nilsson, Soli and Sullivan 1994). These sentences have also been shown to exhibit high test-retest reliability (Nilsson, Soli and Sullivan 1994). The HINT sentences were presented via a commercially-available compact disc recording that uses a male speaker with normal American dialect.
Noise Competition

Correlated (i.e., the same noise source was presented from 45°, 135°, 225°, and 315° azimuth) speech spectrum shaped noise served as the competing stimulus. This noise has been filtered to match the long-term average speech spectrum of the HINT sentences (Nilsson, Soli and Sullivan 1996). This type of noise is typical of the acoustic spectra of everyday listening situations (Crandell, 1991; Plomp, 1986). Additionally, speech spectrum shaped noise has the most deleterious effect on speech recognition for both young and old individuals with normal hearing and hearing impairment relative to other types of noise sources (Nilsson, Soli and Sullivan 1994; Prosser Turini and Arslan 1990). The competing stimulus was presented through the second channel of the HINT compact disc recording.

Procedures

At both sites, Reception Threshold for Sentences (RTS) in noise testing were conducted in a double-walled sound-treated booth [1.9 m (height) × 2.5 m (width) × 2.7 m (length)] using a clinical audiometer (GSI-61). The HINT sentences were presented from a loudspeaker positioned at 0° azimuth located one meter from the study participant (figure 2). At Site I, this loudspeaker was a Tannoy model 600 loudspeaker while at Site II it was a RCA Pro-X44AV loudspeaker. The Phonak TX3 HandyMic FM transmitter was placed on a microphone stand located 3 inches from this loudspeaker at a height of 0.5 meters (figure 2) to simulate an ideal user position (as might be utilized with a boom microphone) (Crandell, Smaldino and Flexer 1995). Testing was conducted with the FM transmitter in the SuperZoom position, which is the Phonak recommended setting for maximum speech recognition in noise. Correlated speech spectrum shaped noise was presented from four loudspeakers positioned at 45°, 135°, 225°, and 315° azimuths (figure 2). All loudspeakers were located one meter from the study participant, which is within the critical distance. These loudspeakers were Definitive Technology BP 2X loudspeakers at Site I and RCA Pro-X44AV loudspeakers at Site II. All loudspeakers were single element loudspeakers. To ensure consistency in the signals, daily calibration of the speech stimuli and noise competition were conducted at the center of the subject's head with the subject absent via a Quest 1500 sound level meter at Site I and via a Quest 1900 Precision sound level meter at Site II.

An adaptive procedure was utilized to assess the RTS in noise. This procedure has been shown to have a higher reliability and validity than percent correct perception procedures (Crandell and Boney, submitted for publication). Additionally, ceiling or floor effects are not a limitation in this procedure as they are in percent-correct procedures (Nilsson, Soli and Sullivan 1994). In the adaptive procedure, the noise level was held constant at 65 dBA and the intensity level of the sentences was varied to determine a 50% accuracy level. A noise level of 65 dBA is typical of noise levels present in many everyday listening environments (Blair 1977; Ross and Giolas 1971; Sanders 1965). For each listening condition, the subject was presented with 20 sentences, consisting of two HINT sentence lists. The first sentence of the list was repeated until an intensity level is chosen in which the subject could repeat the sentence with 100% accuracy. At that point, the intensity level was varied in 4 dB increments for the first five sentences, depending on the participant’s response, and then in 2 dB increments for the last 15 sentences. To calculate the RTS in noise, the intensity level that would be utilized for the 21st sentence, if there were to be one, was predicted based on the participant’s response on the 20th sentence. The RTS in noise was determined by calculating the average of the intensity levels of sentences 5 through 21.

Reception thresholds for sentences in noise were determined for subjects under five different listening
conditions. These listening conditions were: (1) binaural unaided; (2) binaural Phonak Claro 311 dAZ BTE hearing aids alone in omnidirectional mode; (3) binaural Phonak Claro 311 dAZ BTE hearing aids alone in directional mode; (4) binaural, but fit with one Phonak Claro 311 dAZ BTE hearing aid utilized with one Phonak MicroLink FM receiver in the FM only mode and one Phonak Claro 311 dAZ BTE hearing aid in the omnidirectional microphone mode in the opposite ear (half of the subjects utilized the FM on the right ear and half on the left ear) and (5) binaural Phonak Claro 311 dAZ BTE hearing aids utilized with two Phonak MicroLink FM receivers in the FM only mode. All conditions and sentence lists were randomized to avoid order effects. In addition, no list was repeated to reduce potential learning effects.

Results

Mean RTS for each listening condition at each site are presented in figure 3 (solid bars are Site I; stripped bars are Site II). A repeated-measures analysis of variance (ANOVA) was conducted to determine if there was any overall statistical significance between the mean RTS across the five listening conditions at the two sites. The ANOVA revealed a statistically significant difference between listening conditions at Site I ($F_{4,84} = 299.01, p = 0.000$) and at Site II ($F_{4,88} = 293.13, p = 0.000$). Since there proved to be a statistical significance between the listening conditions, Least Significant Difference (LSD) multiple comparison procedures (at an alpha level of $p = 0.05$) were performed to determine where significant differences existed. These post-hoc procedures revealed that:

1. Subjects at both sites obtained the poorest speech recognition scores in the unaided listening condition ($p = 0.000$). The mean RTS for this condition was 4.9 dB ($\pm 4$ dB) for Site I and 7.4 dB ($\pm 5.9$ dB) for Site II. The poorer RTS at Site II is attributable to the poorer air conduction thresholds for the subjects at Site II in comparison to the air conduction thresholds at Site I.

2. These mean RTS when utilizing the hearing aids in the omnidirectional microphone mode ($\text{Mean}_1 = 0.1$ dB [$\pm 3.5$ dB], $\text{Mean}_2 = 2.9$ dB [$\pm 2.3$ dB]) was significantly better than the unaided listening condition ($p = 0.000$). In other words, the mean RTS improved by approximately 5 dB with the use of binaural hearing aids in the omnidirectional microphone mode over the unaided listening condition.

3. The directional microphone mode on the hearing aid ($\text{Mean}_1 = -1.1$ dB [$\pm 3.5$ dB], $\text{Mean}_2 = -0.5$ dB [$\pm 1.8$ dB]) yielded significantly better performance than the condition with the hearing aids in the omnidirectional microphone mode ($p_1 = 0.011$, $p_2 = 0.000$) and the unaided listening condition ($p = 0.000$). Stated otherwise, the utilization of hearing aids in the directional microphone mode improved speech recognition in noise by 1.2 dB at Site I and by 3.4 dB at Site II over the omnidirectional microphone condition.

4. The condition with the binaural hearing aids used with one FM receiver in the FM only mode ($\text{Mean}_1 = -15.3$ dB [$\pm 6.1$ dB], $\text{Mean}_2 = -17.4$ dB [$\pm 4.9$ dB]) resulted in significantly better speech recognition performance than either of the hearing aid conditions ($p = 0.000$). On average, subjects improved by 14.2 dB at Site I by 16.7 dB at Site II with the use of one FM receiver over the use of two hearing aids alone in the directional microphone mode. However, it should be noted that performance in this condition was significantly poorer than the condition with two FM receivers ($p_1 = 0.000$, $p_2 = 0.000$).

5. The best speech recognition scores were obtained when the subjects used binaural hearing aids with two FM receivers in the FM only mode ($p \leq 0.001$). The mean RTS for this condition was $-18.0$ dB ($\pm 4.3$ dB) for Site I and $-19.8$ dB for Site II.
(±4.7 dB) for Site II. This performance was on average 2.7 dB and 2.5 dB better at Site I and II respectively than performance in the condition with one FM receiver.

Independent-sample t-tests were conducted for each condition across the two sites. Test results revealed that there were no statistically significant differences between the two sites in terms of mean RTS for all listening conditions except for the condition with the two hearing aids alone in the omnidirectional microphone mode (p = 0.002). For this listening condition, the subjects at Site I (Mean = 0.07 dB) obtained a significantly better RTS than the subjects at Site II (Mean = 2.9 dB), which results in a difference of 2.8 dB between the two sites.

**Discussion**

Prior studies suggest that individuals with SNHL have significant difficulties understanding speech, especially in noisy or reverberant listening environments (Crandell 1991; Dubno, Dirks and Morgan 1984; Hawkins and Yacullo 1984; Suter 1985; Helfer and Wilber 1990; Helfer and Huntley 1991; Needleman and Crandell 1995, Killion 1997a; Moore 1997). In general, individuals with hearing impairment require the speech signal to be 4 to 18 dB higher than extraneous background noise in order to obtain speech recognition scores similar to individuals with normal hearing (Killion 1997a; Moore 1997). The individuals in this study required a SNR of approximately 5 dB in the unaided listening condition at Site I and 7 dB at Site II. This finding correlates well with past investigations. Killion (1997b), for example, suggests that individuals with pure-tone averages of 40 dB HL (which is the average PTA loss of the subjects in Site I in this study) typically require a SNR of approximately 5 dB in order to obtain 50% correct on the Speech-In-Noise (SIN) test when the signal is presented at 70 dB HL or at a level of "loud, but OK" (Killion 1997a). For individuals with PTA consistent with Site II, a SNR between 6–7 dB would be necessary to reach the 50% criterion.

Mean speech recognition scores were significantly better at both sites in the condition with the hearing aids in the omnidirectional microphone mode than in the unaided listening condition. Few studies have reported these two conditions with current hearing aid technologies (Nabelek and Mason 1981; Duquesnoy and Plomp 1983; Welzl-Muller and Sattler 1984). This finding, however, is reasonable given the magnitude of hearing loss and the enhancement of the auditory signal particularly that of the higher frequencies, provided via amplification. With the amplification of sound provided through the use of hearing aids, the primary signal was made more audible allowing for improved comprehension of the speech signal than without the use of the hearing aids. In fact, Nabelek and Mason (1981) demonstrated that some individuals obtain improved speech recognition with the use of hearing aids over the unaided listening condition in noisy environments. Overall, individuals with hearing impairment required a +3 dB SNR in order to reach 50% criterion on the Modified Rhyme Test (Bell, Kreul and Nixon 1972) in the unaided listening condition. With the use of binaural amplification, these same individuals only required a ~1 dB SNR to reach the same level of performance (i.e., a 4 dB improvement). Additionally, Shanks, Wilson, Larson and Williams (2002) recently examined speech recognition in noise in the unaided listening condition and with a single-channel ITE hearing aid equipped with an omnidirectional microphone programmed as peak-clipping (PC), compression limiting (CL), and wide dynamic range compressing (WDRC). Results revealed all three hearing aid circuits provided a significant improvement in speech recognition over the unaided listening condition. This improvement in speech recognition over the unaided listening condition was greatest at the lowest presentation level (52 dB SPL). Recall that in the current study an adaptive procedure was utilized suggesting that speech was presented near the patient’s threshold of audibility.

The mean RTS obtained at Site I was significantly different that the mean RTS obtained at Site II for the condition with binaural hearing aids in the omnidirectional microphone mode. In this listening condition, the subjects at Site I (Mean = 0.074 dB) obtained significantly better RTS than the subjects at Site II (Mean = 2.9 dB). On average, the subjects at Site I had better pure-tone averages than the subjects at Site II. Recall that this difference in PTA between the two sites was statistically significant both ears (p = 0.000). Hence, this is the likely cause of the discrepancy in RTS scores between the two sites for this listening condition.

Speech recognition performance with the use of the directional microphone was significantly better than with the omnidirectional microphone at both
sites (2.8 dB at Site I and 3.4 dB at Site II). This 
finding is consistent with prior studies (Hawkins and 
Yacullo 1984; Valente, Fabry and Potts 1995; Gravel, 
Fausel, Liskow and Chobot 1999; Ricketts and Dhar, 
1999; Pumford, Seewald, Scollie and Jenstad 2000; 
Valente, Schuman, Potts and Beck 2000; Amlani 
the speech recognition in noise ability of 47 adults 
with mild to moderate SNHL using five different 
hearing aids. Speech recognition was assessed via the 
HINT test sentences, where speech was presented 
from 0° azimuth and uncorrelated cafeteria noise was 
presented at 65 dBA SPL from 30°, 105°, 180°, 225°, 
and 330° azimuth. In the condition using single-
channel analog BTE hearing aids, the mean RTS for 
the directional microphone mode of the hearing was 
approximately −1.2 dB. This study yielded a mean 
directional advantage (RTS of the omnidirectional 
microphone mode minus the RTS of the directional 
microphone mode) of 2.2 dB. Additionally, Amlani 
(2001) conducted a meta-analysis of 74 studies evalu-
ating the speech recognition performance of hearing 
aids equipped with directional microphones. In this 
meta-analysis, a weighted average SNR of −2.6 dB 
(CI95 = ±1.1 dB) was obtained. This weighted average 
corresponds well with the mean RTS obtained in the 
directional microphone listening condition in this 
study. Amlani (2001) calculated a weighted dir-
ctional advantage of 4 dB (CI95 = 0.8).

Although prior studies have obtained improve-
ments with the directional microphone relative to 
the omnidirectional microphone in terms of speech 
recognition in noise by as much to 6 to 8 dB, the 
improvement with the directional microphone in this 
experiment was not as great (Valente, Fabry and 
Potts 1995; Gravel, Fausel, Liskow and Chobot 1999; 

There are a few possible reasons for this finding. As 
mentioned previously, the location and number of 
noise sources in a listening environment can signif-
ically impact the effectiveness of a directional micro-
phone (Ricketts 2000B; Valente, 2000; Gnewikow, 
directly compared the speech recognition in noise util-
izing ITE hearing aids in the omnidirectional micro-
phone mode and in the directional microphone mode 
in two different listening conditions: (1) ideal, in 
which the primary speech signal is presented at 0° 
azimuth and the noise originates from 180° azimuth 
and (2) diffuse, in which the primary speech signal is 
presented at 0° azimuth and the noise originates from 
45°, 135°, 225°, and 315° azimuth (which is the noise 
source configuration used in this study). Results 
revealed a significant improvement in speech recogni-
tion in noise with the dual-microphone directional 
microphone compared to the omnidirectional micro-
phone (3.3 dB). This improvement, however, was 
significantly greater in the ideal listening condition 
compared to the diffuse listening condition (0.5 dB). 
Additionally, Ricketts (2000a) noted a loss in directiv-
ity with hearing aids operating in the directional 
microphone mode with larger vent sizes. In this 
study, vent size was chosen based on audiometric 
configuration and patient comfort. Many of these sub-
jects used relatively large vent sizes because of slight/
mild hearing losses in the low frequencies. Therefore, 
a loss of directivity of the devices may have occurred 
as a result of these larger vent sizes. Certainly, this 
issue requires further study.

Speech recognition in noise was significantly bet-
ter in the FM only condition (monaural and binaural) 
than any hearing aid (omnidirectional and dual-
microphone) at both sites. That is, the mean differ-
ence between the monaural FM and the hearing aids 
in the omnidirectional microphone mode was 15.4 dB 
and 20.3 dB at Site I and Site II respectively and 14.2 
and 16.9 dB for the directional microphone com-
parison. For the binaural FM setting, the mean dif-
ference between FM and the hearing aids in the 
omnidirectional microphone mode was 18.1 dB and 
22.7 dB for Site I and Site II respectively and 16.9 dB 
and 19.3 dB for the directional microphone com-
parison. These finding agree well with the few previ-
ous studies that have examined this issue. In the 
Hawkins (1984) study, the FM only conditions pro-
vided a significant improvement over the all the hear-
ing aid conditions (15.3 dB). The parallel between 
these two studies is not surprising given that proxim-
ity of the FM transmitter to the desired signal 
reduces the effects of noise, distance, and reverber-
ation in such a way that hearing aids are unable to 
do. Unlike the Hawkins (1984) study, however, a bin-
aural advantage was demonstrated with the use of 
the FM system in this experiment by approximately 
3 dB. This binaural advantage was most likely a result 
of the use of two FM receivers (true binaural). In the 
Hawkins (1984) study, binaural FM input was 
delivered through the use of one FM receiver creating 
a diotic signal. Additionally, this binaural advantage 
is consistent with prior studies regarding the benefits 
of binaural hearing and binaural amplification 
(Markides 1977; Nabelek and Mason 1981; Hawkins
and Yacullo 1982; Feuerstein 1992; McCullough and Abbas 1992). Past studies have reported a binaural advantage of 2 to 3 dB when individuals with hearing impairment listen in noise (Markides 1977; Nabelek and Mason 1981; Feuerstein 1992; McCullough and Abbas 1992). To illustrate, Nabelek and Mason (1981) evaluated the speech recognition in noise ability of 21 subjects with bilateral mild sloping to moderate SNHL. Results revealed that these subjects performed 5.9 to 7.2% better in the binaural listening condition than in the monaural listening condition. Given that the PB-PI function of PB words is about 3% per dB, this finding suggests an improvement of 2 to 3 dB when an individual with hearing impairment listens with two ears versus one ear. This binaural advantage remains with the use of amplification. Hawkins and Yacullo (1984) evaluated speech recognition in noise ability of 11 subjects with bilateral symmetrical mild to moderate SNHL utilizing monaural and binaural hearing aids. In this study, subjects obtained significantly better speech recognition scores when utilizing binaural amplification by 2 to 3 dB over the use of monaural amplification. Hence, it is not surprising that our subjects also performed similarly with two FM receivers over the use of one FM receiver.

Clinical Relevance

This study has important implications for the clinical management of patients with SNHL. As previous studies suggest, the majority of individuals with hearing impairment obtain improved speech recognition in noise with the use of hearing aids with directional microphones. There is, however, high individual variability in this finding (Killion, Schulein, Chistensen, Fabry, Revit, Niqette and Chung 1998; Ricketts and Mueller 2000). Unfortunately, at this time, no clear predictor exists regarding which individuals will obtain this improvement in speech recognition and which will not. In fact, Ricketts and Mueller (2000) examined the impact of audiometric slope, magnitude of high-frequency hearing loss, and speech recognition performance in noise using omnidirectional and directional test conditions on 80 subjects. None of these factors proved to be significant predictors of benefits with a directional microphone.

All of the study participants at the two sites obtained significantly better speech recognition performance in noise with the use of FM system in either the monaural or binaural mode. Despite this improved performance in noise, relatively few patients are being fit with FM technology. In fact, recent estimates suggest that less than 5% of adults with hearing aids also use FM technology (Crandell and Smaldino 2000). With these documented improvements in speech recognition ability in noise, it is imperative that clinical audiologists offer FM technology as a viable option for communication to their patients when discussing treatment options regarding hearing impairment. The audiologist should describe FM technology, its usage, and its documented benefits with their patients. This type of technology should be further reviewed and demonstrated in hearing aid orientation programs.

Additionally, this study provides documentation regarding the degree of speech recognition performance obtained under various FM technology arrangements. This information is critical for audiologists when counseling their patients regarding FM system applications in “everyday” communication situations. For instance, the vast majority of study participants realized better speech recognition performance in noise with the use of the hearing aids equipped with two Phonak MicroLink FM receivers rather than with just one FM receiver. The mean difference in RTS between these two conditions in this study was 2.7 dB at Site I and 2.4 dB at Site II. Hence, just as the majority of patients benefit from the use of binaural hearing aids, audiologists can now counsel their patients that the majority of individuals with hearing impairment will perform better in background noise if the signal of interest (e.g. speech) is at the microphone of the FM transmitter and the FM receivers are fit bilaterally rather than monaurally.

Limitations of the Study

Despite the significant findings in this investigation, there are several limitations. First, the majority of study participants were older adults. Recall that the median age of this study sample was 73 years. Hence, these results cannot be generalized to other age groups, especially to children. Gravel, Fausel, Lisow and Chobot (1999) evaluated the speech recognition in noise ability of children, ranging in age from 4 to 11 years, with bilateral, mild to severe SNHL using omnidirectional and dual-microphone technology. Study results revealed that the dual-microphone condition provided a significant improvement in speech recognition for both words and sentences over the omnidirectional condition by
4.7 dB, which is approximately 3 dB poorer than that obtained by adults under similar conditions. Additionally, these investigators reported that older children and children with greater receptive vocabularies could tolerate more noise (4 dB) in both microphone conditions than younger children could. Hence, one should not assume that children would obtain the same speech recognition performance in noise that was obtained in this study since only adults served as subjects.

A second limitation of this study is that one cannot assume that the findings in this investigation are comparable to “real-world” performance with these devices. Although attempts were made to simulate a “real-world” environment by utilizing semi-diffuse noise, the conditions utilized in this study are still not typical of “real-world” listening environments. Recall that speech recognition testing was conducted in a sound-treated environment, which results in reduced effects from reverberation. Hawkins and Yacullo (1984) evaluated the speech recognition in noise ability of individuals using both omnidirectional and directional microphone technology under three different reverberation times (0.3 s, 0.6 s, 1.2 s). As reverberation time increased, performance degraded. It is logical to assume that the performance obtained in this study with the hearing aids would also degrade with increased reverberation. In “real-world” listening environments, speech is not always presented at 0 azimuth nor is noise presented from a static location or from the rear/sides of the listener; therefore various modifications of the speech and noise presentations may alter speech recognition results with the experimental devices (Ricketts, 2000b). Additionally, recall that the FM transmitter was located three inches from the primary loudspeaker. This distance represents an ideal placement for the FM transmitter, thereby minimizing the effects of noise, reverberation, and distance on the speech signal. Unfortunately, this placement may not occur at all times in a “real-world” environment. At this time, we do not know what the effects of microphone distance would have on speech recognition performance in noise. Also, this experiment was only conducted with the use of correlated speech spectrum shaped noise as the noise competition. Hence, no information is available regarding the effects of speech recognition had the signals been presented in an uncorrelated fashion (which is probably more typical of their everyday listening environments) nor is there information regarding other types of noise that may be encountered by the individual with hearing impairment in their everyday listening environments. Additionally, FM listening conditions were only evaluated with the FM transmitter in the SuperZoom setting. The speech recognition benefit obtained in the study is likely not to be similar when other FM transmitter microphone settings are utilized.

Finally, this investigation was conducted with just one particular model of hearing aid and one model FM system. Currently, a number of other companies manufacture FM system technology that is compatible with hearing aid technology, including Phonic Ear and AVR Communications Ltd. Additionally, the Phonak MicroLink is compatible with hearing aids manufactured by 16 other companies. Since several studies have reported a wide degree of electroacoustic variability with the use of various FM components, it should not be assumed that all brands and models of these devices would produce the same speech recognition results obtained in this study (Freeman, Sinclair and Riggs 1980; Bess, Sinclair and Riggs 1984; Thibeodeau and Saucedo 1991).

**Summary**

Overall, results of this investigation reported that FM technology significantly improved speech intelligibility over the hearing aid conditions, both in omnidirectional and directional listening conditions. Additionally, speech recognition performance is further enhanced by almost 3 dB using of two FM receivers rather than one FM receiver. These data suggest that FM technology will offer significantly better communicative performance in adverse listening situations than any type of hearing aid microphone configuration. Stated otherwise, for maximum speech intelligibility in noise to occur for listeners with SNHL, the hearing healthcare professional should consider the utilization of FM technology and counsel their patients how to maximize their use in everyday listening situations.

**AUTHOR’s NOTE:** A major segment of this paper was submitted and has been subsequently accepted for publication in the *Journal of the American Academy of Audiology*. For that manuscript, the third author of this manuscript was the primary author.
